INTRODUCTION

The incidence of pediatric ovarian torsion is estimated to be 4.9 cases per 100 000 girls per year.1 Half of pediatric patients with ovarian torsion are induced by an ovarian mass, including cystic and solid masses.2–4 Torsion of normal ovary, which can be caused by functional and hemorrhagic cysts, has also been reported.3 In spite of recent progress in diagnostic imaging, an early diagnosis of ovarian torsion is sometimes difficult due to variable clinical symptoms and non-specific imaging findings.3,5 Establishing predictive clinical pictures reflecting ovarian torsion is crucial for the diagnosis and determining the optimum therapeutic strategy to preserve its function in the current practice of pediatric surgery.

However, it often takes time for patients to consult to our institution because there are many isolated islands in our medical area. In addition, in most cases, pediatric surgeons are not the physicians performing the initial evaluation. It is therefore sometimes difficult to distinguish whether an imaging modality, such as an abdominal ultrasound examination, shows torsion or not. We started this study with the aim of obtaining simpler indicators in the primary and secondary care areas.

The aim of this study was to analyze the risk of torsion and oophorectomy of ovarian masses. We retrospectively analyzed the clinical features of 49 consecutive patients (55 episodes) with ovarian masses experienced at our institution to explore the risk factors for irreversible torsion of ovarian masses requiring oophorectomy.

METHODS

We reviewed 58 ovarian masses (55 episodes) in 49 non-neonatal patients treated from April 1984 to March 2017. We retrospectively analyzed the pathological diagnosis, age at admission, tumor size, white cell count at admission, C-reactive protein (CRP) level at admission, and duration of abdominal pain (from onset to surgery) based on the medical records.

Statistical analyses

Mann-Whitney U test and Fisher’s exact test were used for the statistical analyses.

ETHICS

This study was performed in accordance with the Ethical Guidelines for Medical and Health Research Involving Human Subjects by the Ministry of Health, Labour and Welfare of Japan in 2014 and complies with the 1964 Declaration of Helsinki (revised in 2013).

was approved by the local ethics committee of our institution (No 27-119).

RESULTS
Patient characteristics
The affected ovary was on the right side in 33 episodes (63.5%) and left in 19 episodes (36.5%) except for synchronous bilateral lesions in three patients (three episodes). Six of the patients had bilateral pathology. Three patients had synchronous onset, and three had metachronous onset. Among the 15 cases with torsion, the affected ovary was on the right in 10 cases (66.7%) and left in 5 (33.3%).

The median age of the 55 episodes was 10.5 years old (range 1.0–23.0). The symptoms at the diagnosis of the 55 episodes were abdominal pain in 33 (60%), and nine cases were diagnosed by chance. In the 33 episodes whose chief complaint was abdominal pain, 15 ovaries were torsed, and 18 were not torsed. The median age of the 15 patients with torsion was 9.5 years old (range 4.0–15.0). The most frequent age distribution was from 5 to 10 years of age, being seen in 46.7% of this series of 55 episodes.

The pathological diagnosis and clinical outcome of the 55 ovarian masses
The clinical outcome of the 58 ovarian masses is shown in Table 1. Forty-five (80%) masses were neoplastic tumors, and the remaining 13 were non-neoplastic tumors. Forty-five tumors were resected, and 13 cystic masses were resected or enucleated, leaving the normal ovarian tissue. All masses, regardless of pathology, were finally diagnosed after surgical intervention. The pathological diagnoses for the 58 ovarian masses were as follows: 30 mature teratomas (51.7%), 2 immature teratomas (grade II, 3.5%), 5 serous/mucinous cystadenomas (8.6%), 2 immature teratomas (grade III, 3.5%), 5 dysgerminomas (8.6%), 1 yolk sac tumor (1.7%), 7 simple cysts (12.1%), and 6 hemorrhagic cysts (10.3%). In total, 8 malignant lesions (13.8%), including dysgerminoma, immature teratoma (grade III), and yolk sac tumor, were confirmed.

Fifteen ovaries (25.9%) were torsed at operation, and 43 (74.1%) were not. Among the 15 torsed ovaries, 5 were tumors with solid component and the remaining 10 were cystic. There were significant differences in the torsion ratio between cystic masses and tumors including solid components (p=0.00003156). The pathological diagnoses of the torsed masses were as follows: five simple cysts, five hemorrhagic cysts, and five mature teratomas. Oophorectomy was performed in 20 masses, including 8 mature teratomas (40%), 1 immature teratoma (5.0%), 1 mucinous cystadenoma (5.0%), 4 dysgerminoma (20.0%), 1 yolk sac tumor (5.0%), and 5 hemorrhagic cysts (25.0%).

Clinical characteristics of patients with torsion versus non-torsion ovaries
Clinical characteristics of patients with torsion versus non-torsion ovaries were shown in Table 2. There were no significant differences in the age, CRP value at admission, and mass size between the two groups. White cell counts on admission were significantly higher in the torsion cases (10.7 x 10^9/L) than in the non-torsion cases (6.7 x 10^9/L) (p=0.002). The cut-off white blood cell (WBC) value for torsion was calculated to be 9.6 x 10^9/L according to receiver operating characteristic (ROC) curve analysis (figure 1).
A comparison of the torsion and non-torsion masses presenting with abdominal pain is shown in table 3. Among the 33 patients whose chief complaint was abdominal pain, 15 (45.5%) were with torsion, and 18 (54.5%) were not. There were no significant differences in the age, tumor size, CRP value at admission, or duration of abdominal pain (from onset to surgery). The white cell count on admission was significantly higher in the torsion cases ($10.7 \times 10^9/L$) than in the non-torsion cases ($6.5 \times 10^9/L$) ($p=0.007$). The cut-off WBC value for torsion was calculated to be $9.6 \times 10^9/L$ according to ROC analysis (figure 2).

Preserved versus non-preserved ovaries with torsion

A comparison of the preserved and non-preserved ovaries with torsion is summarized in table 4. Among the 15 masses with torsion, 8 (53.3%) ovaries were successfully preserved while the other 7 (46.7%) who underwent ovarian resection include oophorectomy in 3 and salpingo-oophorectomy in 4. Comparing the preserved with non-preserved cases, the duration of abdominal pain was significantly shorter in the preserved cases (24 hours) than in the non-preserved cases (144 hours) ($p=0.026$). The cut-off symptom duration affecting ovary preservation was calculated to 36 hours according to ROC analysis.

The radiological features regarding ovarian torsions

Nine of 15 torsion cases had available imaging data. Abdominal ultrasound sonography (US) was performed in all nine cases, and CT was also performed in 7 cases (77.8%). We did not perform transvaginal US because of the young age of the patients. US showed 4 simple lesions (44.4%), 5 complex lesions for hemorrhagic cysts, and mature cystic teratomas (55.6%). Seven cases (77.8%)
of acute appendicitis, abdominal pain gradually becomes stronger, and there are many cases with fever (64%) and vomiting (42.4%) than ovarian torsion. In addition, the white cell count is about $10^9/L$, which tends to be higher than ovarian torsion. Comparing the torsion and non-torsion ovaries presenting with abdominal pain, Rey-Bellet Gasser et al reported that laboratory tests were not helpful for diagnosing the torsion of ovarian masses, while Graif and Itzchak reported that the white cell count is high in cases of torsed ovarian masses. Our results suggest that only white cell count may be helpful for detecting torsion. A white cell count of $>9.6 \times 10^9/L$ may indicate torsed ovarian masses, and it may be best at least to perform laparoscopic exploration. The white cell count was significantly higher in the torsion cases than in the non-torsion cases ($p=0.0133$) and the cut-off value was $9.6 \times 10^9/L$. White cell counts may help decide if surgery is indicated in cases of suspected ovarian torsion.

The majority of ovarian torsion occurred to the ovarian tube or ovary. There was only one case in which the blood flow in the ovary was evaluated by color Doppler US, and a normal blood flow was noted. Abdominal pain lasting (hours): the duration of abdominal pain (from onset to surgery).

**SURGICAL PROCEDURE FOR OVARIAN TUMOR**

The surgical procedure was laparotomy in 37 (67.3%) and laparoscopy in 18 (32.7%). Laparoscopy was introduced at our institution in 2006, after which point 14 of 32 episodes (43.8%) underwent laparoscopy-assisted surgery. Five cases were converted to open oophorectomy by a Pfannenstiel incision. Surgery was performed in 65.5% and performed emergently in 34.5%. Teratomas and simple cysts were treated with enucleation by laparoscopic surgery or laparotomy with a Pfannenstiel incision, whereas malignant tumors are subjected to oophorectomy by laparotomy or laparoscopy.

**DISCUSSION**

Abdominal pain with unilateral ovarian enlargement should always be suspected to indicate ovarian torsion in girls. In general, the precise diagnosis of torsion is based on enhanced CT findings. However, pediatric outpatient clinics do not always have access to such imaging modalities especially in a district hospital or in remote islands. We therefore analyzed the basic components of clinical findings that suggest ovarian torsion for a timely transfer to the tertiary center where pediatric surgery is available.

The most common symptom of ovarian torsion is abdominal pain. In our case of ovarian torsion, sudden abdominal pain (100%) and vomiting (20%) were characteristic. Although the strength of abdominal pain ranged from very strong and sharp to dull or mild pain, all cases reported a sudden onset. In contrast, there were no cases with chief complaints of a fever; furthermore, while the white cell count was increased (median 10.7 (range 5.2 to 18.2) $\times 10^9/L$), the elevation was only slight. Therefore, a differential diagnosis from gastrointestinal diseases, such as appendicitis and acute gastroenteritis, is necessary. Gastrointestinal disease is usually accompanied by inflammation and a high white cell count. In the case
the need for surgery, and the cut-off white cell count was 9600/μL in all ovarian masses and 9600/μL in ovarian masses with abdominal pain.
