Comparison between hepaticojejunostomy and hepaticoduodenostomy after excision of choledochal cyst in children: a cohort study

Johann Paulo Suico Guzman, Leandro L Resurreccion III, Marcus Lester R Suntay, Renato G Bernaldez

ABSTRACT

Objective Hepaticojejunostomy (HJ) and hepaticoduodenostomy (HD) are commonly used biliary reconstruction techniques after choledochal cyst excision. HD has been suggested to be a more physiologic alternative during reconstruction. The objective of this study is to compare operative time, hospital stay, morbidity (leak, cholangitis, ileus, and obstruction), and mortality between HJ and HD after cyst excision.

Methods This is a 14-year retrospective cohort study of pediatric patients (≤18 years old) who underwent choledochal cyst excision and subsequent biliary reconstruction at the Philippine Children’s Medical Center. Data were taken from inpatient charts, operative technique, OPD logbook, readmission, and OPD charts.

Results There were 122 patients: 56% HD and 44% HJ. Majority were female (72%), with 1:2.6 male to female ratio. The average age was 36.1 months, with a mean follow-up of 32.8 months (range 6 months–14 years). The most common cyst was type I (87%). Operative time was longer for HJ compared with HD (321.3 vs 203.6 min; p=0.000). Hospital stay was longer with HJ compared with HD (7.7 vs 6.8 days; p=0.002). Mortality was low at 1.6% while morbidity was at 13.9% in both groups. Although morbidity was higher among those who underwent HD, there was no significant difference between the two procedures. Anastomotic leak (4%) and cholangitis (7.4%) were observed in HD, and ileus (7.4%) was observed in the HJ group.

Conclusions In our series, HD provided less operative time and hospital stay than with HJ. We did not observe bile gastritis after HD as compared with others. It is suggested that longer follow-up is needed to confirm such findings.

INTRODUCTION

The reconstruction for biliary enteric continuity after choledochal cyst resection favors the use of a Roux-en-Y anastomosis because it offers lesser complications of cholangitis and anastomotic leaks.1 The treatment of choledochal cyst commonly involves excision of the cyst, but the biliary enteric continuity can be achieved with different reconstruction techniques.2 Some surgeons prefer to use hepaticojejunostomy (HJ) anastomosis with an Roux-en-Y limb, while others use hepaticoduodenostomy (HD) reconstruction. Advocates of using HJ anastomosis state that it has lesser complications of bile leak afforded by less tension on the suture line by the Roux limb, and it affords enteric diversion away from the biliary tree, thus preventing cholangitis postoperatively.3 The advantages of HD include faster operative time because it only has one anastomosis compared with three in a jejunal reconstruction, and faster recovery of bowel function due to less bowel manipulation.4 It is thought that using the duodenum as conduit for anastomosis entails greater incidence of reflux, leading to higher incidence of postoperative cholangitis, anastomotic stenosis, and rarely carcinoma development.5

The incidence of cholangitis after biliary reconstruction is largely attributed to the ascending passage of enteric bacteria to the biliary tract. A Roux-en-Y HJ uses a defunctionalized long limb that affords enteric diversion from the biliary tree. A duodenal conduit for HD theoretically has a higher incidence of cholangitis because of the direct access of enteric bacteria from the duodenum to the biliary tree. Hsieh et al6 provided this explanation of ascending cholangitis in rat models using Escherichia coli strains injected by gel electrophoresis in the biliary enteric conduits.

Using the duodenum in the biliary reconstruction has some advantages of lesser operative times and lesser incidence of leaks because of the single anastomosis. The requirements for a safe HD is that the duodenum should...
be sufficiently mobilized to be able to reach the common bile duct stump for a tension-free anastomosis. If there is tension in the anastomosis, it is contraindicated and it should be converted to HJ.\(^2\)

In a 15-year review of Silva-Baez \textit{et al}\(^2\) last 2015 in patients who underwent HJ anastomosis, they have found a 25\% complication rate compared with those who had HD anastomosis, which had a rate of 16.6\%. Complications include cholangitis, leak and postoperative reflux. In their series, they have found no mortalities, and they support the use of the duodenum as a safer alternative and offer lesser complications to using Roux limb reconstruction.\(^3\)

**METHODS**

**Research design and description of the study procedure**
This is a 15-year retrospective cohort study of patients 18 years old and below who were diagnosed with choledochal cyst and who underwent cyst excision and subsequent biliary reconstruction at the Division of Pediatric Surgery, Philippine Children’s Medical Center. The study period included patients from 2002 up to 2016. There were two groups of patients: one group included those who had HJ and the other group those who underwent HD. Patients’ operative records were recovered from the Division of Pediatric Surgery’s monthly operative census and from the hospital’s medical records.

A total of 122 patients were included in the study. The size of the common bile duct during ultrasound in all of these patients ranges from 1 cm to 9 cm. The type of reconstruction depended on the following factors: biliary anatomy, the surgeon’s technical familiarity of the procedure and the patient’s preoperative status. The type of biliary reconstruction was primarily decided by the surgeon’s preference; there was no randomization done. There were three cases done laparoscopically and the rest were done with open surgery.

**Operative techniques**
After standard cyst excision in open cases, during HD reconstruction the duodenum is mobilized by Kocherization. The remaining proximal common hepatic duct after cyst excision is flushed to clear out debris and is anastomosed 2 cm distal to the pylorus using interrupted absorbable 4–0 sutures. In cases where HJ was used, the Roux limb is created by transsecting the jejunum 15 cm distal to the ligament of Treitz and brought up to the hilum 40 cm in length. The jejunojejunostomy is done, completed with a single-layer anastomosis with 4–0 absorbable sutures to the end of the proximal jejunum to the side of the Roux limb, making sure that the Roux limb brought up is 40 cm. The biliary enteric continuity is completed with an end-to-side fashion 1 cm proximal to the end of the limb.

In the select three cases that were done laparoscopically, the size of the CBD measured by ultrasound ranged from 1 cm to 2 cm, which was relatively smaller. The procedure was carried out with four ports: 10 mm umbilical port and three 3.5 mm working ports at the right flank, left flank and the left subcostal area. This technique is similar to the one performed by Liem \textit{et al}\(^8\)\(^9\).

After ligation of the cystic artery and duct, the proximal gall bladder was suspended transabdominally to aid the exposure of the hilum. The cyst is dissected circumferentially using cautery and transacted near the junction of the cystic duct and the common hepatic duct. The distal cyst was ligated with clips as it tapers near the junction of the pancreatic duct. In all laparoscopic cases, HD was used and was performed similarly as described earlier in open surgery.

These data were recorded in the preoperative logbooks and they were used in the data collection. Data on follow-up of patients were based on the out-patient department (OPD) census logbooks, readmission in patient charts and OPD charts.

The inclusion criteria were all pediatric patients (younger than 18 years old) who underwent excision of choledochal cyst with subsequent biliary reconstruction. The exclusion criteria were patients who underwent diversion procedures for choledochal cysts, patients who had intrahepatic choledochal cysts (type V) where complete excision is not possible and patients who had biliary reconstruction for malignant reasons.

All patients who underwent surgery were followed up at regular intervals. The Pediatric Gastroenterology Section, along with the Pediatric Surgery Service, saw patients postoperatively. Patients’ follow-up schedule at OPD Surgery entails them to go to the OPD 2 weeks after surgery and monthly thereafter. The OPD records of these patients were then used in the data collection; their clinical status, development of new symptoms, morbidity incurred and length of follow-up were recorded. For those patients who were lost to follow-up, they were called through the telephone number provided on the data identification sheet in the patient’s chart to assure compliance to follow-up. During the phone interview, patients were asked to follow up at the OPD Surgery. The last date of follow-up was based on the last follow-up at the OPD. If the patient was readmitted, data from the readmission charts were taken and recorded.

Summary statistics were presented in the tables as median quantitative variables and as n (%) for categorical outcome measures. Checks for homogeneity of sample population and normality assumption were performed. Mann-Whitney U test was used to compare averages. Chi-squared test was used to compare proportions. Statistical significance was based on p value ≤0.05.

**RESULTS**
There were 122 patients who underwent choledochal cyst excision and eventual biliary reconstruction, 56\% HD and 44\% HJ. Three patients who had HD underwent laparoscopic excision and reconstruction, whereas the rest were done in open procedures. Majority were female.
(72%), with a 1:2.6 male to female ratio. The average age of the cohort was 36.1 months old; older patients underwent HD (p=0.244). The most common cyst was type I (87%). The characteristics of patients in both groups were homogeneous with respect to age, gender, and type of cyst (table 1). The average operative time was 249.2 min, longer for HJ compared with patients who underwent HD (321.3 vs 203.6 min; p=0.000). Patients stayed in the hospital for an average of 7.1 days±1.5 (SD), longer for those who underwent HJ (7.7 vs 6.8 days; p=0.002). The mean follow-up in the cohort of patients was 32.8 months (range 6 months–14 years).

Mortality rate was low at 1.6%, while morbidity was at 13.9%. Although the rate was higher among those who underwent HD, there was no significant difference between the two procedures (table 2).

Table 3 enumerates the different causes of mortality and morbidity in both groups of reconstruction. In the HD group, two patients died. One patient died of sepsis secondary to anastomotic leak. In this patient in whom a leak was considered, the presentation was sepsis, with signs of peritonitis and pneumoperitoneum. The other mortality was in a patient who presented with cholangitis. In this patient, the diagnosis was made and the patient underwent an emergency revision of the reconstruction, but subsequently succumbed to sepsis postoperatively.

In both groups of reconstruction, anastomotic leak was diagnosed with bilious drainage from the drain site, and in all of these cases, except one, they were successfully managed conservatively. Conservative management included delaying enteral feeding, institution of antibiotics, and delayed removal of the drain. There was one case of anastomotic leak in the HD group in which there was a revision of the reconstruction using a Roux limb. This patient presented with signs of peritonitis, fever and continued bilious drainage output.

There was no patient who had cholangitis during follow-up in the HJ group, whereas there were five cases of cholangitis in the HD group. In all of these cases, they were also successfully managed conservatively with antibiotic treatment.

There was one case of pancreatitis in the HD group, who presented postoperatively with abdominal pain and elevated pancreatic enzymes. In this patient, there was resolution of pancreatitis and was discharged unremarkable.

There was one case of intestinal obstruction in the HJ group in need of re-exploration. During exploration, the cause of the obstruction was an internal hernia which was secondary to the mesenteric defect during the creation of the Roux limb.
There was one case of upper gastrointestinal bleed in the HD group. The patient presented during follow-up with hematochezia necessitating endoscopy. During endoscopy, they noted variceal bleeding and bleeding gastritis with no note bile reflux in the stomach. Conservative management included placing the patient on proton pump inhibitors and rubber band ligation.

Ileus was more common in the HJ group as the reconstruction entails more bowel manipulation during the reconstruction. In all of these patients, they presented with delayed return of bowel function, abdominal distension, and radiologic findings of ileus.

**DISCUSSION**

The use of duodenum on enteric continuity is associated with lesser operative times and shorter hospital stays compared with using a Roux limb for reconstruction. In this study there is a statistical difference between the HD group and the HJ group in both operative time (203.6 min vs 321.3 min) and hospital stay (6.8 days vs 7.7 days). This may be due to the fact that single anastomosis was involved in the first group compared with the multiple anastomoses in the reconstruction using the Roux limb. Although morbidity and mortality rates are not statistically significant in both groups, there are specific complications that are unique in each type of reconstruction. Although the two deaths in the HD group did not reach statistical significance, there is a higher frequency of anastomotic leaks (p=0.781) in the HD group. Various studies state that the limitation of the HD is that there may be tension during the procedure when using the duodenum in the reconstruction, making the use of Roux limb suitable for reconstruction. In our series, the leaks observed in HD were successfully managed conservatively, indicating leaks occurring on these patients are minor. But caution should be exercised when signs of peritonitis and hemodynamic instability develop because these warrant exploration and revision of the anastomosis. Ultimately, intraoperative findings will dictate surgical judgment on which type of reconstruction to use; if too much tension is encountered in the procedure, a Roux limb is a surgically sound option during such cases.

One theoretical advantage of using a Roux limb during the reconstruction is the lower incidence of reflux of enteric stream to the biliary tree, lowering the chance of cholangitis postoperatively. This was also observed in this study; none of the patients who underwent HJ developed cholangitis compared with those who underwent HD. Cholangitis can occur in these patients if stricture formation occurs. According to Dimou et al, in a group of 3374 patients, the cumulative incidence of stricture was 12.5% at 2 years, and the mean time to stricture diagnosis was 16.8±21.6 months (median=8.5 months). In our series, patients developed signs of cholangitis within 2 years after surgery. The time needed for stricture formation supports the follow-up among patients who underwent HD for the development of cholangitis later on. Surgeons argue that HJ provides a more durable reconstruction by following the recommendations suggested by Yamataka et al. These are (1) end-to-end anastomosis if possible; (2) if end-to-side anastomosis is unavoidable, the common hepatic duct should be anastomosed as close as possible to the closed end of the blind pouch; (3) careful selection of the vascular supply to the Roux jejunal limb; and (4) the length of the Roux limb should not be predetermined, but individualized. In our series, we observed an intestinal obstruction which was secondary to mesenteric defect during the reconstruction of the Roux limb. It may be also reasonable to be meticulous and repair for iatrogenic mesenteric defects created during the reconstruction.

As noted in this study, there was higher incidence of cholangitis in the HD group compared with the cases from the HD group and none from the HJ group. In the three cases, ulcerations were noted, which were all secondary to *Helicobacter pylori* with no evidence of bile reflux. This finding is in contrast to our Japanese counterparts. We have not adopted a policy of routine endoscopy in all cases after HD. It can be argued that most endoscopically proven bile reflux gastritis can be minimally asymptomatic and we have not found routine endoscopy of value in our setting. Liem et al also reported a 14.3% incidence of bilious gastritis in their series performed laparoscopically.

In our series, it is notable that, although it did not reach statistical significance, there is a higher frequency of gastritis with no note bile reflux in the stomach. Conservative management included placing the patient on proton pump inhibitors and rubber band ligation.

In our series, it is notable that, although it did not reach statistical significance, there is a higher frequency of gastritis with no note bile reflux in the stomach. Conservative management included placing the patient on proton pump inhibitors and rubber band ligation.

Ileus was more common in the HJ group as the reconstruction entails more bowel manipulation during the reconstruction. In all of these patients, they presented with delayed return of bowel function, abdominal distension, and radiologic findings of ileus.

**DISCUSSION**

The use of duodenum on enteric continuity is associated with lesser operative times and shorter hospital stays compared with using a Roux limb for reconstruction. In this study there is a statistical difference between the HD group and the HJ group in both operative time (203.6 min vs 321.3 min) and hospital stay (6.8 days vs 7.7 days). This may be due to the fact that single anastomosis was involved in the first group compared with the multiple anastomoses in the reconstruction using the Roux limb. Although morbidity and mortality rates are not statistically significant in both groups, there are specific complications that are unique in each type of reconstruction. Although the two deaths in the HD group did not reach statistical significance, there is a higher frequency of anastomotic leaks (p=0.781) in the HD group. Various studies state that the limitation of the HD is that there may be tension during the procedure when using the duodenum in the reconstruction, making the use of Roux limb suitable for reconstruction. In our series, the leaks observed in HD were successfully managed conservatively, indicating leaks occurring on these patients are minor. But caution should be exercised when signs of peritonitis and hemodynamic instability develop because these warrant exploration and revision of the anastomosis. Ultimately, intraoperative findings will dictate surgical judgment on which type of reconstruction to use; if too much tension is encountered in the procedure, a Roux limb is a surgically sound option during such cases.

One theoretical advantage of using a Roux limb during the reconstruction is the lower incidence of reflux of enteric stream to the biliary tree, lowering the chance of cholangitis postoperatively. This was also observed in this study; none of the patients who underwent HJ developed cholangitis compared with those who underwent HD. Cholangitis can occur in these patients if stricture formation occurs. According to Dimou et al, in a group of 3374 patients, the cumulative incidence of stricture was 12.5% at 2 years, and the mean time to stricture diagnosis was 16.8±21.6 months (median=8.5 months). In our series, patients developed signs of cholangitis within 2 years after surgery. The time needed for stricture formation supports the follow-up among patients who underwent HD for the development of cholangitis later on. Surgeons argue that HJ provides a more durable reconstruction by following the recommendations suggested by Yamataka et al. These are (1) end-to-end anastomosis if possible; (2) if end-to-side anastomosis is unavoidable, the common hepatic duct should be anastomosed as close as possible to the closed end of the blind pouch; (3) careful selection of the vascular supply to the Roux jejunal limb; and (4) the length of the Roux limb should not be predetermined, but individualized. In our series, we observed an intestinal obstruction which was secondary to mesenteric defect during the reconstruction of the Roux limb. It may be also reasonable to be meticulous and repair for iatrogenic mesenteric defects created during the reconstruction.

As noted in this study, there was higher incidence of cholangitis in the HD group compared with the

CONCLUSION

In our series, the use of the duodenum in the reconstruction after cyst excision shows shorter operative times and hospital stays with similar morbidity and mortality rates compared with using a Roux limb reconstruction, similar to those reported in the literature. We have not observed bile gastritis in our series. Due to the retrospective nature of this study and the relatively short mean time of follow-up (2.7 years), it is recommended to have a longer observation time. The use of routine endoscopy in all cases with HD could still be debatable, and comparison between routine and selective endoscopy could be an area of active study.
